

An Overview of Air- And Bone-Conducted CE-Chirp Stimuli

Andrew Stuart, Ph.D., CCC-A, Aud(C)
Department of Communication Sciences &
Disorders
East Carolina University
Greenville, NC, USA

Learner Objectives

- After this course, participants will be able to:
 - understand differences between air- (AC) and bone-conducted (BC) CE-Chirps and traditional click stimuli.
 - understand differences between AC CE-Chirp Octave Band stimuli and traditional tone burst stimuli.
 - describe similarities/differences in ABRs to CE-Chirps and CE-Chirp Octave Band stimuli versus traditional click and tone burst stimuli.

Webinar Overview

- Introduction
- The CE-Chirp® Versus Click Stimulus
- The CE-Chirp® Octave Band Versus Tone Burst Stimulus
- Stimulus Parameter Effects:
 - CE-Chirp®
 - CE-Chirp® Octave Band Stimuli
- Clinical Applications
- Questions

3

East Carolina University

4

What is the ABR?

- The ABR “reflects bioelectrical potential arising from the auditory nerve and brainstem in response to acoustic short-duration sounds (*transient signals*).”
– ASHA (2004)

7

- A normal ABR waveform recorded from adults consists of a series of 5 to 7 peaks that occur within the first 10 ms after the onset of a *transient stimulus*.

Sampath et al. (2016). Brainstem auditory evoked potentials for intraoperative neurophysiological monitoring. J Neuroanaesthesiol Crit Care 2016;3, Suppl S1:1-3

8

Clinical Applications of ABRs

- Differential Diagnosis/Evaluations
 - Integrity of auditory nerve and brainstem pathway
 - Auditory processing
- Newborn Hearing Screening
- Estimation of Behavioral Thresholds

9

Why A Transient Stimulus?

- The ABR is an onset response.
- The rapid onset of the transient stimulus is key in generating the synchronous firing of numerous auditory 8th nerve fibers and brainstem neurons that underlies the response.
- The “click” is the most commonly used transient signal.

10

Typical Air-conducted Click

(Hall, 2015)

11

gsi
E-LEARNING

What's Good About The Click?

- Can provide an assessment of 8th nerve and auditory brainstem integrity.
 - i.e., can rule out possible neurological involvement.
- Click ABR thresholds correlate quite well with hearing sensitivity in the 2000 to 4000 Hz range.

12

gsi
E-LEARNING

Estimating the Audiogram by the ABR

- “...ABR to tonal stimuli can be successfully recorded in most clinical environments and provide reasonable accuracy estimates of 500 to 4000 Hz pure-tone behavioral thresholds...”
– (Stapells & Oates, 1997)

15

Typical Air-conducted Tone Burst

(Hall, 2015)

E-LEARNING

Derived Band ABRs

(Don et al., 1997)

- The frequency components along the basilar membrane are shown from base to apex.
- Each band contributes to the standard ABR.
- But the low frequency components are phase canceled!

21

gsi
E-LEARNING

Temporal Alignment: Output

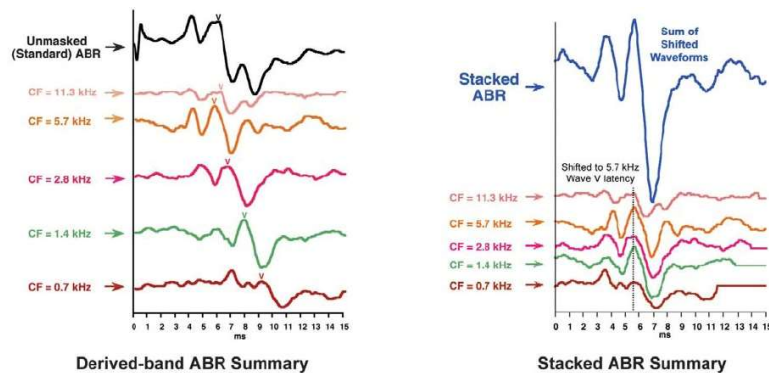

- One way is to align the activity along the cochlear is to temporally align derived band ABRs.
 - i.e., output compensation
- The Stacked ABR is formed by first generating derived-band ABRs, temporally aligning wave V, and then summing stacked responses.
 - (Don et al., 1997, 2005).
- Aligning the derived-band ABRs eliminates phase cancellation of lower frequency activity.

22

gsi
E-LEARNING

The Stacking Method

(Don et al., 2005)

23

gsi
E-LEARNING

Temporal Alignment: Input

- Another way is to align the activity along the cochlear is to time-shifting the different frequency components of the click stimulus.
 - i.e., input compensation
- The order of the frequency components in the stimulus is based on the tonotopic organization of the basilar membrane.

High-synchrony cochlear compound action potentials evoked by rising frequency-swept tone bursts

Shore, E. and Nuttal, L. (1985)

Journal of Neurophysiology, 50, 1000-1010

The auditory compound action potential (CAP) represents synchronous VIBRA nerve activity. This synchronous activity is evoked by a large portion of the cochlear partition. However, the observation that only auditory nerve units with short latencies to synchronous activity in the CAP complex of the CAP (Dau et al., 1993, 1994) could be recorded into the CAP response, the present study uses tone bursts of exponentially rising frequency to systematically activate synchronous discharges of VIBRA nerve fibers along the length of the cochlear partition. The latencies of the CAP response are calculated to be the latencies of the delay line characteristics of the given pig cochlear partition. The cochlear response theoretically causes a constant phase displacement of a large portion of the cochlear partition as one tone. Compound action potentials recorded in response to the rising frequency sweeps were compared to CAPs evoked by corresponding falling frequency sweeps and clicks. Analysis of the CAP waveforms showed that the CAPs evoked by rising and falling frequency sweeps were composed of two distinct components. The first component was the synchronous response to the rising frequency sweep, and the second component was the asynchronous response to the falling frequency sweep. A further test of the hypothesis was made by using high-pass stimuli to isolate the contribution of discrete cochlear locations to the CAP "response". CAPs. Latency functions of the CAPs for clicks and falling frequency sweeps showed progressive increases in latency as the cutoff frequency of the high-pass filter was lowered. The latency of the CAP for these stimuli showed no latency reduction with delay (Dau and Dau, 1993).

INTRODUCTION

The cochlear compound action potential (CAP) represents synchronous firing of VIBRA nerve fibers in response to an acoustic stimulus. A stimulus of short duration and high rate in the frequency domain (e.g., a click) elicits the CAP. CAPs are usually more readily than signals of long duration and narrow in the frequency domain (e.g., a pure tone or tone burst). As a result, CAPs have been used in the past to study the properties of the cochlear partition. However, the traveling wave delay on the cochlear partition produces a latency dispersion among VIBRA nerve units, including presynaptic (Carr et al., 1981; Johnson, 1981; Nuttal et al., 1981). This has been shown that only auditory nerve units with short latencies to synchronous activity in the CAP complex of the CAP (Dau et al., 1993, 1994) could be recorded into the CAP response. Additionally, Johnson (1981) showed that the threshold CAP response reflects activity of only the most sensitive units.

In this report, we assess the effects of an acoustic signal, a stimulus of rising frequency, which theoretically causes a phase displacement of a large portion of the cochlear partition as one tone. The CAPs evoked by rising frequency sweeps were compared to CAPs evoked by corresponding falling frequency sweeps and clicks. Analysis of the CAP waveforms showed that the CAPs evoked by rising and falling frequency sweeps were composed of two distinct components. The first component was the synchronous response to the rising frequency sweep, and the second component was the asynchronous response to the falling frequency sweep. A further test of the hypothesis was made by using high-pass stimuli to isolate the contribution of discrete cochlear locations to the CAP "response". CAPs. Latency functions of the CAPs for clicks and falling frequency sweeps showed progressive increases in latency as the cutoff frequency of the high-pass filter was lowered. The latency of the CAP for these stimuli showed no latency reduction with delay (Dau and Dau, 1993).

DISCUSSION

The CAPs evoked by rising and falling frequency sweeps were composed of two distinct components. The first component was the synchronous response to the rising frequency sweep, and the second component was the asynchronous response to the falling frequency sweep. A further test of the hypothesis was made by using high-pass stimuli to isolate the contribution of discrete cochlear locations to the CAP "response". CAPs. Latency functions of the CAPs for clicks and falling frequency sweeps showed progressive increases in latency as the cutoff frequency of the high-pass filter was lowered. The latency of the CAP for these stimuli showed no latency reduction with delay (Dau and Dau, 1993).

CONCLUSIONS

The CAPs evoked by rising and falling frequency sweeps were composed of two distinct components. The first component was the synchronous response to the rising frequency sweep, and the second component was the asynchronous response to the falling frequency sweep. A further test of the hypothesis was made by using high-pass stimuli to isolate the contribution of discrete cochlear locations to the CAP "response". CAPs. Latency functions of the CAPs for clicks and falling frequency sweeps showed progressive increases in latency as the cutoff frequency of the high-pass filter was lowered. The latency of the CAP for these stimuli showed no latency reduction with delay (Dau and Dau, 1993).

The Claus Elberling -Chirp®

(Elberling et al, 2007, 2010; Elberling & Don, 2008, 2010)

- Designed using a delay model based on derived-band ABR latencies.
- The electrical CE-Chirp® has a flat amplitude spectrum within five octave-bands ranging from 350 to 11,300 Hz.
- Four octave-band filtered versions of the CE-Chirp® are also implemented with the center frequencies 500, 1000, 2000, and 4000 Hz.
 - The octave-band chirps are obtained by decomposing the broad-band CE-Chirp®.

26

The CE-Chirp®

A rising frequency or "low-frequency leading" stimulus that compensates for the cochlear traveling wave delay!

27

CE-Chirp® & Click Time/Amplitude Waves

28

Some Temporal Issues

(Kristensen & Elberling, 2012)

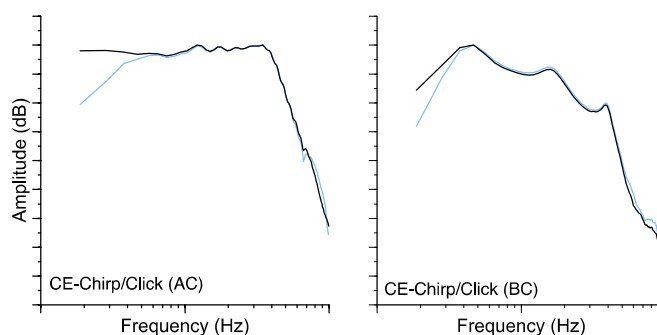

- The 10,000 Hz component of the CE-Chirp® is delayed by 1.5 ms to align ABR latencies to the chirps with the latencies to the click in normal-hearing subjects.
- The 0 ms point on the time axis for the acoustical waveforms indicates the start of the data collection and also the temporal reference for all latency measures.

CE-Chirp® Octave Band: Temporal Characteristics (GSI, 2013)

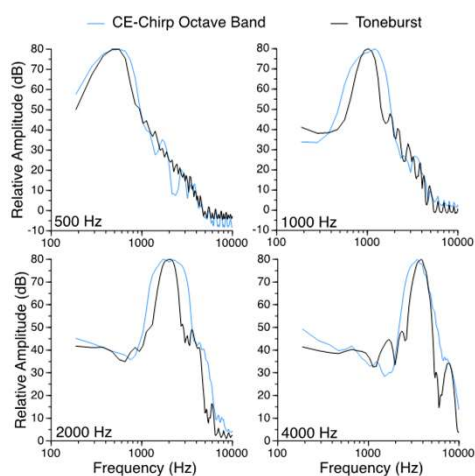

- The timing of each CE-Chirp® Octave Band stimulus is derived from the timing of the same component in the CE-Chirp®.
- Notice that the tone burst presentation starts at 0 ms, while the CE-Chirp® Octave Band stimulus presentation precedes 0 ms.

33

CE-Chirp® Octave Band & Tone Burst Spectra

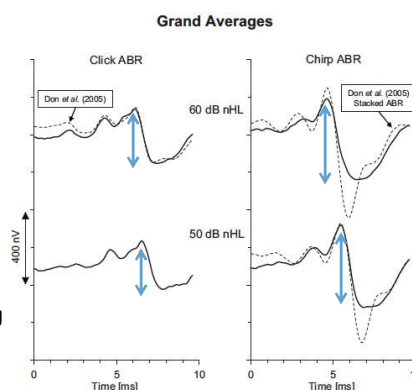

34

Why Use the CE-Chirp®?

- Using a CE-Chirp® has been shown to increase the amplitude of the ABR in adults compared to the amplitude in response to a click.
 - Elberling et al, 2007; Elberling and Don, 2008; Don et al, 2009; Elberling et al, 2010; Cebulla and Elberling, 2010; Elberling and Don, 2010; Kristensen & Elberling, 2012; Elberling et al., 2012

(Elberling & Don, 2008)

35

ECU & The CE-Chirp®

- We were interested in using the CE-Chirp® with neonates:
 - Compare neonate ABRs to air- (AC) and bone-conducted (BC) CE-Chirp® and click stimuli.
 - Compare neonate ABRs to AC CE-Chirp® octave band and tone burst stimuli.
 - Compare neonate and adult ABRs to AC CE-Chirp® and CE-Chirp® octave band stimuli.

Effect of Stimulus and Number of Sweeps on the Neonate Auditory Brainstem Response

Andrew Stewart and Karen M. Cash

Abstract: The purpose of this study was to determine the effect of stimulus and number of sweeps on the neonate auditory brainstem response (ABR). The study was conducted in a hospital setting with 10 newborn infants. The ABR was recorded using a standard protocol. The results showed that the ABR amplitude increased with the number of sweeps and decreased with the stimulus intensity. The ABR was also affected by the stimulus duration and the stimulus rate. The ABR was recorded for each infant, and the results were compared to the normal range. The ABR was found to be within the normal range for all infants.

Keywords: Auditory brainstem response, neonate, stimulus, number of sweeps, ABR.

Introduction: The auditory brainstem response (ABR) is a measure of the electrical activity of the auditory pathway in response to an auditory stimulus. It is a non-invasive method of assessing the integrity of the auditory pathway in newborn infants.

Methods: The ABR was recorded using a standard protocol. The stimulus was a click sound, and the number of sweeps was varied. The ABR was recorded for each infant, and the results were compared to the normal range.

Results: The ABR amplitude increased with the number of sweeps and decreased with the stimulus intensity. The ABR was also affected by the stimulus duration and the stimulus rate.

Conclusion: The ABR was found to be within the normal range for all infants.

Discussion: The results of this study suggest that the ABR is a reliable method of assessing the integrity of the auditory pathway in newborn infants.

52

CE-Chirp® Observations

- Wave V amplitudes to AC and BC CE-Chirp® are significantly larger than those evoked to standard click.
- Wave V latency differences exist between the AC and BC CE-Chirp®.

53

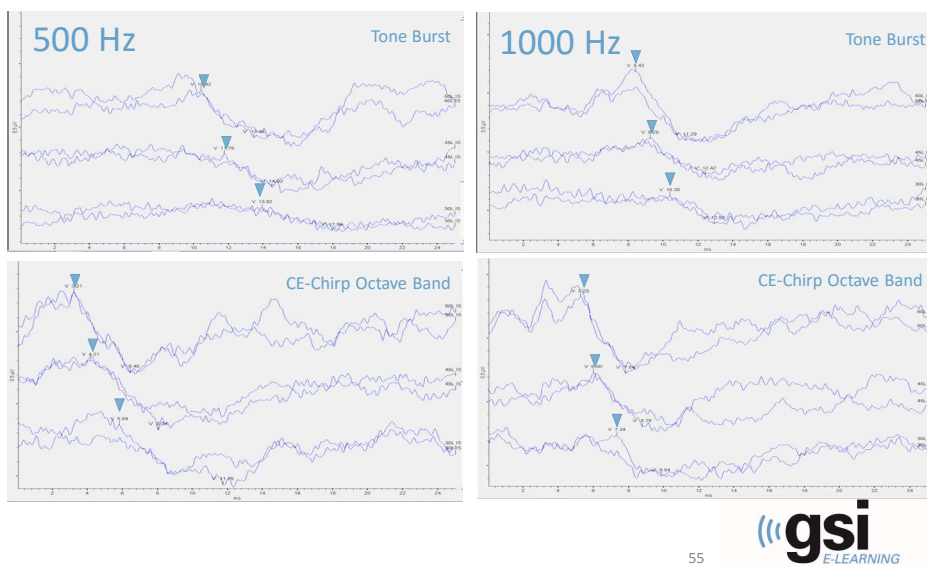

- AC and BC ABRs can be reliably evoked with low intensity 30 dB nHL CE-Chirp® and a fast rate of 57.7/s, similar to the current parameters of newborn hearing screenings.
- With the CE-Chirp®, wave V can be detected with 1/4 the amount of stimulus presentations required for the click.

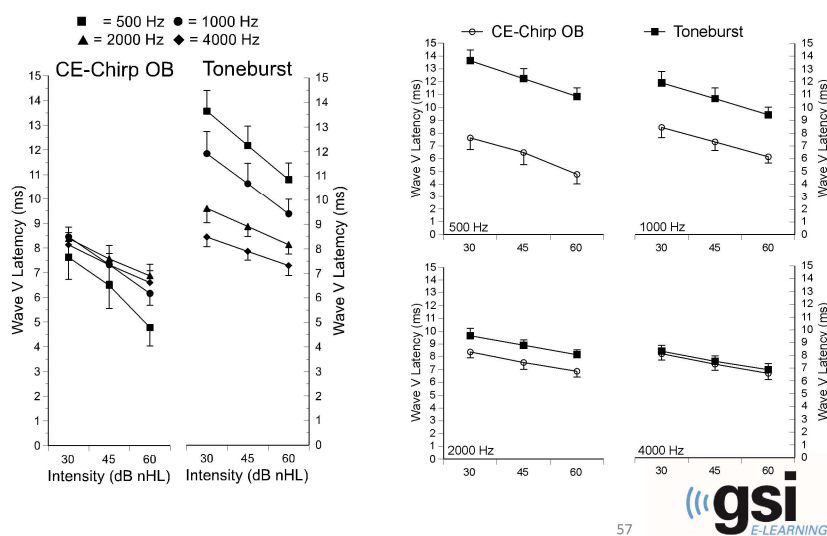

54

ABR Waveforms: Tonal Stimuli

ABR Wave V Latency

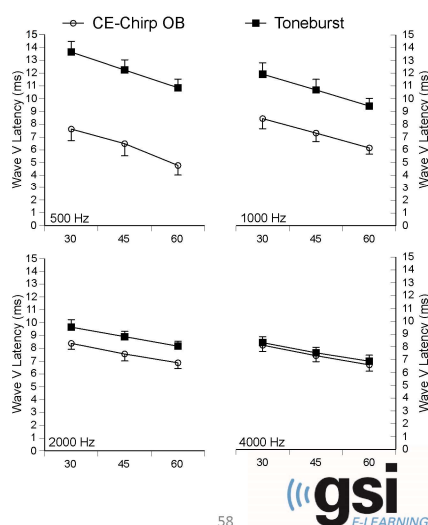

57

CE-Chirp® Octave Band Observations: Wave V Latency

- Wave V latencies significantly earlier to CE-Chirps® Octave Bands versus tone bursts.

— Related to input delay for “rising frequency” chirp.

— (Cebulla et al., 2014; Kristensen & Elberling, 2012)

58

Latency/Frequency Reversal!

Conclusions

- Wave V amplitudes to AC and BC CE-Chirp® stimuli are significantly larger than traditional stimuli.
- Wave V latency differences exist between CE-Chirp® stimuli and traditional stimuli.
- Test time can be reduced.
- ABRs to AC and BC CE-Chirp® stimuli are reliable.
